ELECTRE TRI

ABSTRACT

This work addresses the problem of determining the most suitable sites for locating biogas plants using dairy manure as feedstock, specifically in the Entre-Douro-e-Minho Region in Portugal. A Multicriteria Spatial Decision Support System is developed to tackle this complex multicriteria decision-making problem, involving constraints and many environmental, economic, safety, and social factors. The approach followed combines the use of a Geographic Information System (GIS) to manage and process spatial information with the flexibility of Multicriteria Decision Aid (MCDA) to assess factual information (e.g. soil type, slope, infrastructures) with more subjective information (e.g. expert opinion). The MCDA method used is ELECTRE TRI, an outranking-type method that yields a classification of the possible alternatives. The results of the performed analysis show that the use of ELECTRE TRI is suitable to address real-world problems of land suitability, leading towards a flexible and integrated assessment.

1. Introduction

Livestock farms produce excreta in large quantities, which traditionally have been used directly as manure to fertilize the land. However, in some cases, the disposal methods can cause environmental problems such as odour and water pollution [1]. There is growing interest in installing Anaerobic Digester (AD) to use dairy manure as a biomass resource for both economic value and environmental benefit [2,3]. An AD energy

system promotes methane production, captures and converts it into electricity and heat, and also yields a fertilizer.

Biomass is part of Portugal's renewable primary sources, but in 2008 the relative contribution of Portuguese biogas for the biomass primary energy consumption did not reach 1% [4]. This factor together with the high biogas potential of Portugal shows that this important sector has been somewhat neglected [5].

To promote the development of dairy manure-based bio-energy systems it is essential to find suitable locations for

such development [3]. Land-use suitability analysis is a tool used to identify the most suitable places for locating future land uses according to specific requirements, preferences, or predictors of some activity [6]. Determining suitable land for a particular use is a complex process involving multiple aspects that may relate to biophysical, socio-economic and technical aspects [3].

Choosing an appropriate location for a biogas plant is a task for which Geographic Information Systems (GIS) and Multicriteria Decision Aid (MCDA) are helpful [7–10]. MCDA provides significant support for the generation and comparison of alternatives taking into account the evaluation criteria through an active participation of experts and stakeholders involved in the decision-making process. MCDA offers a set of procedures, techniques and algorithms for structuring decision problems, and designing, evaluating and prioritizing decision alternatives [11,12]. Location problems have strong spatial dimensions, as a large number of spatial variables are involved, such as the proximity to rivers, roads or populations, and spatial characteristics of the region including geology, slope, and soil types among others. GIS are designed to store, manage, analyse and visualize geospatial data required by decision-making processes [13].

A large number of papers concerning multicriteria suitability analysis and GIS have been published (see Refs. [14–19]). More recently, GIS has been combined with MCDA in environment/ecology (e.g. Refs. [20,21]), in undesirable facilities location (e.g. Refs. [22–24]), energy ([25,26]), and location ([27,28]), among other application areas.

In this context, a specific family of Decision Support Systems (DSS) named Multicriteria Spatial Decision Support Systems (MC-SDSS) may provide effective support. MC-SDSS typically includes a set of geographically defined alternatives from which a choice, a ranking or a classification of a set of alternatives is made with respect to a given set of evaluation criteria [17].

In this paper, a spatial multicriteria approach for supporting decision-makers in the process of locating of biogas plants is proposed. Spatial multicriteria analysis requires information on the value of the criteria and geographical location of the alternatives, in addition to the preferences of decision makers. A variety of constraints, as well as economic, environmental and social factors are integrated in this approach to help determine the most suitable sites for installing such bio-energy systems. As an application of the approach proposed in this work, a land suitability map for locating biogas plants was developed for the Entre-Douro-e-Minho (EDM) region in Portugal. The result is a classification of each potential location into one of three categories of suitability: low, medium, or high suitability.

2. Methodology

The MC-SDSS developed for the present study is shown in Fig. 1, encompassing the three phases: intelligence, design and choice, according to the model proposed by Ref. [29]. In the intelligence phase, data is acquired, processed, and an exploratory data analysis is performed. This phase focuses on structuring the problem after which the objectives to pursue

are explored and the evaluation criteria or attributes are selected. The design phase involves data collection and processing, as well as the development of multicriteria analysis through the definition of the relationships between objectives, attributes and preferences of the decision maker [12]. In this phase, specific decision rules are used to evaluate and sort alternatives. The choice phase usually involves formal MCDA-GIS interaction in order to develop a solution set of spatial decision alternatives, with integration of decision analytical techniques and GIS functions. In this phase, alternatives are evaluated in order to derive appropriate recommendations. This general framework for MC-SDSS development is based on the general architecture of spatial multicriteria decision-analysis from Ref. [12], but presents some changes in the Design Phase, such as the iterative application of the ELECTRE TRI to perform MCDA, and uses an innovative way to define the set of alternatives that are evaluated.

2.1. Problem definition

The EDM Region is located in the northwest of Portugal and consists of a set of 10 counties: Viana do Castelo, Barcelos, Esposende, Póvoa de Varzim, Vila Nova de Famalicão, Vila do Conde, Santo Tirso, Trofa, Maia and Matosinhos, with an area of 158,438 km². This region has 1705 dairy farms with more than 100,000 bovine animals, which produce approximately 1.5 million cubic metres of wastewater (solids and liquids) per year.

The dairy sector has significant economic and social importance to this region. However, this activity has generated numerous environmental problems linked to the high spatial concentration of farms and increasing number of animals, either caused by the volume of effluent generated and related impacts on water and soil, or by conflicts with urban areas. These factors, sometimes associated with insufficient storage capacity and sewage treatment, as well as the misuse of equipment and methods of spreading in the soil, result in contamination of crops and waterways, as well as production of unpleasant odours, among other problems.

As pressure from environmental regulations and surrounding community increases, it is important to build a set of ADs for a better manure management in this region. On the other hand, biogas plants belong to the group of undesirable facilities and are considered as NIMBY (not in my backyard) facilities, whose location presents two main problems to be addressed: (i) social opposition and (ii) a large number of social, economic and environmental data that have to be taken into account [30].

2.2. Constraints and factors

Recently, in Portugal, there has been a concern regarding the problem of evaluation of biogas production using different sources, but there is still no legislation defining the location, characteristics and limitations for installation of this type of plants. In this study, we resorted to Portuguese legislation directed to the installation of similar infrastructures (such as solid waste landfill), European legislation, other studies and the contribution of two experts – an agronomic engineer, specialized in the environmental field and GIS applications

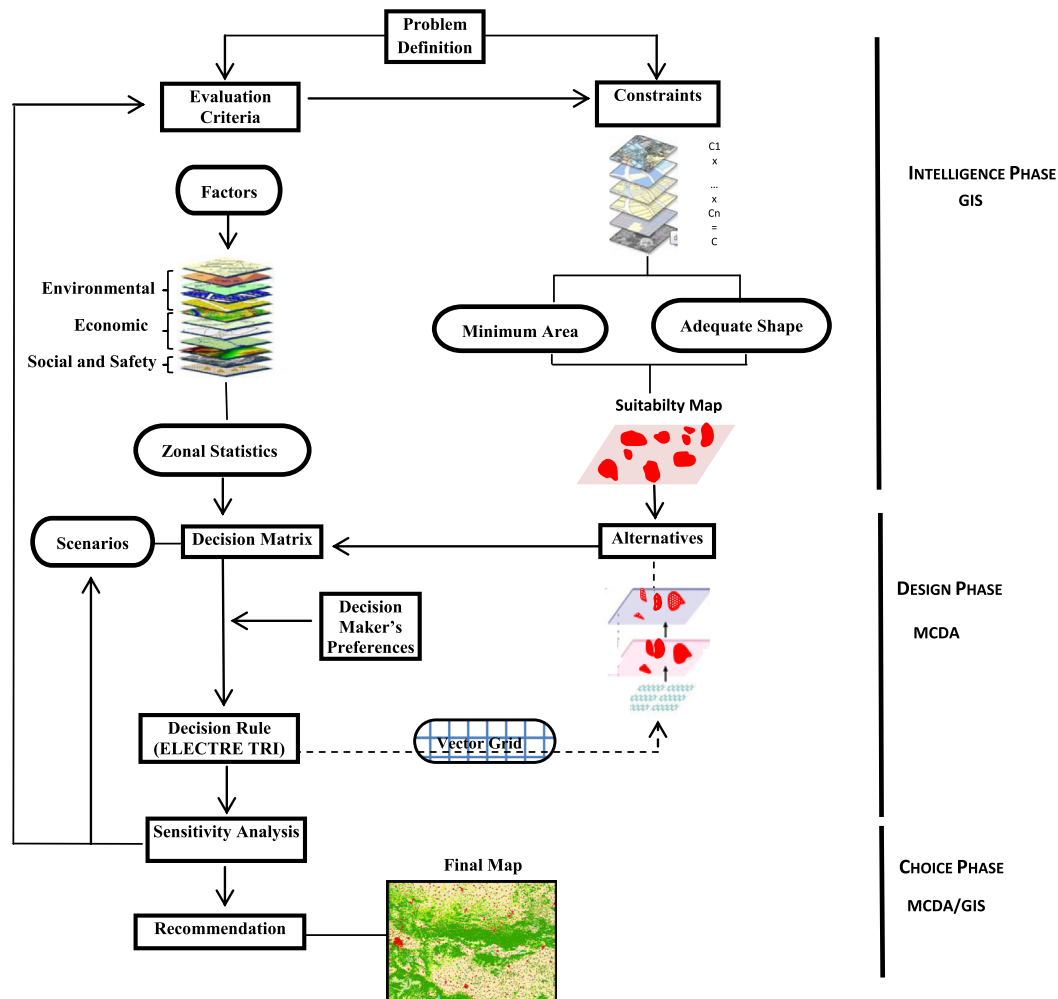

Fig. 1 – Decision flowchart for the spatial multicriteria analysis methodology in this work.

(Expert 1), and another agronomic engineer specialized in Photogrammetry and Remote Sensing (Expert 2), who have developed various works in the region in study.

In the present study 20 criteria (attributes) are involved in the methodological process, either as constraints (or exclusionary criteria) or factors (or non-exclusionary criteria).

We consider seven exclusion criteria, defined in Table 1 by Expert 1 that considered legislation about the implementation of landfills, the Municipal Master Plans and other similar studies such as [3,31,32]. Based on these constraints the GIS obtains independent eligible geographic areas of polygonal shape (referred as polygons from now on) considered as non-excluded or potentially suitable sites, through basic GIS operations of ESRI® ArcGIS® 10 (buffering, boolean logic, etc.) [33]. An additional constraint named “Minimum Area” represents the minimum area of the polygon required for the implementation of a centralized biogas plant. We defined that the implementation of a centralized biogas plant occupies at least 1 ha, based on Expert 1 knowledge and other studies as [34]. The final constraint relates to the physical shape of polygons, which sometimes are not realistic options for the implementation of this type of infrastructure. In this work, we use a shape measure including area and perimeter measures

– the compactness (or circularity ratio). Involving the Expert 2 about different shape measures and [35], a restriction “Adequate Shape” is defined based on a constraint of each polygon area (represented in Table 1). Considering the constraints set, we obtained a suitability map containing the location alternatives.

In this study, the criteria factors are defined by the expert who identified three dimensions: an environmental dimension, an economic dimension, and a social and safety dimension. A biogas plant site should be situated as far away as possible from biophysical elements such as water, and other areas with ecological and agricultural value in order to reduce the risk of contamination and to protect the environment. The use, occupancy and type of the soil also should be considered to minimize the impacts on their use and to reduce risks. Moreover, when considering economic feasibility of a candidate site, the proximity to the electricity network, the proximity to roads and the slope of the terrain are important. At the same time, the biogas plant is considered to have a significant impact on the population living within close proximity to the site, due to concerns such as aesthetics, odour, safety, noise, decrease in property value and health hazards. Therefore the plants should be situated at a

Table 1 – Description of the constraints defined in the suitability analysis.

Constraints		Description
<i>Hard criteria</i>	National ecological reserves, Natura 2000 and Protected Areas	Areas classified as National Ecological Reserve, Protected Areas and Natura 2000 are excluded from the analysis.
	Hydrographic network	To exclude areas which contain or are less than 150 m away from water lines
	Roads and railway	To exclude areas which contain or are less than 70 m away from motorways, regional roads, national roads and rail network.
	Slopes	To exclude areas with slopes greater than 15% or less than 2.5% (avoid areas prone to flooding and high costs of construction)
	Urban, industrial and commercial and infrastructure	To exclude areas which contain or are less than 200 m away from urban, industrial and commercial and infrastructure areas (Airports, port areas and other equipment).
	Built-up areas	To exclude buildings (isolated type, as residential building)
	Electricity grid	To exclude areas whose distance to the very high voltage electrical lines is less than 200 m, the distance to high voltage lines is less than 100 m and the distance to medium voltage lines is less than 50 m (for security reasons).
	Minimum area	Potential sites must have an area of at least 1 ha for implementation of a biogas plant.
	Adequate shape	Exclude polygons that verify the following condition: ($1 \leq \text{area(ha)} \leq 1.5$ and compactness < 0.45) or ($1.5 < \text{area(ha)} < 2.5$ and compactness < 0.25).

considerable distance from urban residential, commercial and industrial areas. In this study, we considered 13 criteria factors (Table 2) defined by the two experts, based in their knowledge and in study [32], where some factors (roads, transmission lines, urban areas, water and slope) are considered.

These factors are mostly quantitative and represented by distances, and so the majority of the derived maps are distance maps. Only two criteria are qualitative (“Occupation and Land Use” and “Agricultural Soils”), given the subjectivity of qualitative criteria, we proceed to its simplification through the use of a rating scale defined by the experts.

2.3. Outranking method

Outranking methods are a type of MCDA methods that are well suited to land suitability assessment and to deal with spatial decision problems since they: (i) permit to consider qualitative evaluation criteria (in addition to quantitative ones) for which preference intervals ratios have no sense; (ii)

permit to consider evaluation criteria with heterogeneous scales such that coding them into one common scale would be very difficult or artificial; (iii) avoid the complete compensation between evaluation criteria; and (iv) require a fewer amount of information from the decision maker [36]. But it is also recognized that these methods are subject to computational limitations with respect to the number of decision alternatives [37]. Outranking approaches require a comparison of all pairs of alternatives along each factor defined. In cases where dealing with large raster datasets these methods reach their computational limits quickly.

In this study the previously identified potential sites (polygons) are the location alternatives to be subject to a multi-criteria evaluation process. Each of polygons has a different shape and area and the occupied space is not homogeneous for each factor. The MCDA method requires numerical values but it is not possible to associate with each polygon a unique value for each factor. To overcome this difficulty we resort to descriptive statistical values and spatialized scenarios. We apply this process again to new smaller

Table 2 – Description of the factors defined in the suitability analysis.

Type	Name	Factors	Objective
<i>Environmental</i>	F1	Distance to the National Ecological Reserve	Maximize
	F2	Distance to protected habitats (Natura 2000 and protected areas)	Maximize
	F3	Distance to the National Agricultural Reserve	Maximize
	F4	Distance to hydrographic network	Maximize
	F5	Occupation and land use (qualitative assessment of adequacy)	Maximize
	F6	Agricultural soils (qualitative assessment of adequacy)	Maximize
<i>Economic</i>	F7	Slope (in %)	Minimize
	F8	Distance to highways, regional and national roads	Maximize
	F9	Distance to the municipal roads and paths	Minimize
	F10	Distance to electricity grid – medium voltage lines	Minimize
	F11	Distance to electricity grid – high voltage	Minimize
<i>Social and safety</i>	F12	Distance to urban, industrial, commercial and infrastructure	Maximize
	F13	Distance to the built-up areas	Maximize

sites inside these classified polygons, created through a vector grid, to obtain a more specified and complete suitability classification.

2.3.1. Decision matrix and spatialized suitability scenarios

In order to obtain a decision matrix indicating the performance of each alternative on each factor, the minimum and maximum values of all factors across each region are computed, using a tool in Spatial Analyst's, the "Zonal Statistics" of ArcGIS®. Although the maximum and minimum values are two extreme measures we consider that using a simple average value as an estimate would be insufficient to address the potentially significant differences between the best and the worst cases.

In order to classify each alternative, the decision matrix is constructed taking into account two scenarios, called "Best" and "Worst" scenarios. The Worst Scenario decision-matrix contains the worst values, i.e., the minimum values of each criterion for each alternative, obtained from the Zonal Statistics tool, if the objective is to maximize, and maximum values, if the objective is to minimize. On the contrary, the Best Scenario decision-matrix contains the maximum values if the objective is to maximize and the minimum values if the objective is to minimize. Thus, two decision matrices associated with two scenarios were obtained, on which the decision rule will be applied. Each of these scenarios has spatial information about each of the factors involved, which is the input for the MCDA method. If the classification is the same in both scenarios, it means that we can classify this alternative in that particular category and so the classification is robust regardless of the location of the plant within this site.

In some polygons there is only one possible location for the biogas plant, whereas in some large polygons there may be several locations where the biogas plant may be implemented. We consider that it is important to study the location of the biogas plant within suitable areas that are comparable in size and that are small enough to be considered homogeneous (i.e., the characteristics of the location should not differ much from one place to another inside a polygon). For this purpose, we create a vector grid that intersects with suitable areas, creating a grid within these sites. The Vector Grid generation process subdivides larger areas into smaller regular polygon cells and allows saving the polygon cells generated as a vector object. For the Grid Generation a tool called ET GeoWizards [38] in ArcGIS® is used. The cell size must be greater than the minimum required area (1 ha) since the grids created in this work will also be considered as possible alternative locations for the biogas plant. In this study, we considered that the cell size of the grid is 2 ha. The grids obtained are intersected with some of this suitable polygons and the intersect results from both have to be re-analysed using the constraints related to the minimum area required and the adequate shape (adapted for this step).

2.3.2. ELECTRE TRI method

The chosen MCDA method is ELECTRE TRI, which is specifically devoted to classification problems and has been used by several authors in environmental problems (e.g. [39–43]).

ELECTRE TRI has been developed for dealing with the so-called sorting problematic, which sorts a set of alternatives

into a set of predefined categories, considering multiple criteria. This assignment of each alternative a_k from a set A to a category or class C_i is undertaken, based on a comparative study between each alternative and the reference profiles that characterize the limits of each category. To assign each alternative to a category, ELECTRE TRI makes use of the outranking concept, building binary relations among each alternative a_k and the profiles b_i and b_{i-1} that bound each category C_i . For the context of this problem, each a_k represents a suitable site to be sorted, and each profile b_i defines a category of suitability. The method assumes that classes are listed in increasing order of preference, e.g., C_1 is the worst category (least suitable for a location).

ELECTRE TRI builds a valued outranking relation S whose meaning is " a_k is at least as good as b_i " [44,45], i.e., it defines an index $\sigma(a_k, b_i) \in [0, 1]$ that represents the degree of credibility of the assertion $a_k S b_i$. The assertion $a_k S b_i$ is considered to be valid if $\sigma(a_k, b_i) \geq \lambda$, λ being a "cutting level" such that $\lambda \in [0.5, 1]$, that is defined as the lowest degree of credibility (σ) for which we can say that a_k outranks b_i [46,47].

According to the pessimistic procedure, which is the one most used in practice [46], the alternative a_k is assigned to the highest category C_i such that a_k outranks b_{i-1} (the category's lower bound) and does not outrank b_i (the category's upper bound). For further details on the algorithm and concepts of this method, see Refs. [44–46,48–51].

2.3.2.1. Decision makers preferences of ELECTRE TRI. In this work ELECTRE TRI classifies the alternatives according to predefined categories which are: Category 1 – low suitability, Category 2 – medium suitability and Category 3 – high suitability. The criteria (factors) considered are those presented in Table 2. ELECTRE TRI will evaluate land-use suitability according to multiple factors considered by a comparison of the category profiles, in order to classify the most suitable sites for implementation of a biogas plant, with the subjective parameter values (that express preferences) being specified by experts, legislation and other studies. The most important subjective parameters are composed of two reference profiles (b_1 and b_2). The reference b_2 defines the set of criteria performance values separating medium and high suitability, whereas reference b_1 defines the limits separating low and medium suitability. Each alternative is compared with these reference profiles. If an alternative outranks b_2 , its suitability is qualified as high. In an analogous way, its suitability is low if it does not outrank b_1 . If the alternative outranks b_1 but does not outrank b_2 , its suitability is qualified as medium. The reference profiles set by the expert are presented in Table 3.

Other subjective parameters are weights (k_j) and three thresholds: indifference (q_j), preference (p_j) and veto (v_j), which are associated with each soft criterion. Weight expresses the relative importance of the criteria. Indifference is the largest difference in performance, for a factor, that may be considered insignificant. Preference is the smallest difference in performance constituting a clear advantage. The veto threshold indicates a difference in performance (discordance) so large that it vetoes an outranking, even if all other criteria agreed to it. In practice, setting a veto threshold allows to specify minimum performances that an alternative has to

achieve to reach a certain category, and that cannot be compensated by excellent performances in other criteria. The indifference, preference and veto thresholds, as well as the criteria weights were obtained directly by considering the responses of experts, as presented in Table 4. The cutting level considered was $\lambda = 0.60$ (in the absence of veto, the criteria

supporting an outranking must represent at least 60% of the total criteria weights).

2.3.2.2. Iterative application of ELECTRE TRI. We begin by applying ELECTRE TRI twice to classify the polygons according to the Best and Worse scenarios, using two decision matrices.

**Fig. 2 – Suitability Map obtained after applying the constraints set.**

If the ELECTRE TRI results (classification) are the same in both scenarios, it means that we can classify this site in the particular category and so their classification is obtained regardless of the location of the biogas plant within this suitable site. In case the classification is different in both scenarios then we create a vector grid that intersects with suitable sites (polygons) that not are classified yet. ELECTRE TRI is applied again, considering now the intersected grid cells as alternatives and the same parameters defined previously. Again, two matrices for each scenario (Worst and Best) and the classification of each one of grids according to defined categories are obtained but, since the areas are smaller, it is expected that the differences between the two scenarios decrease. At the end, the most suitable alternatives are identified and a map of the most suitable sites is obtained.

3. Results

3.1. Obtaining the suitability map

This methodological approach began by considering the seven exclusion criteria defined to obtain potentially suitable sites. In this case study, 521 polygons (independent geographic regions) were obtained. However, only 380 polygons have the minimum area required, i.e., 141 polygons were excluded for having an area smaller than 1 ha. Taking into consideration the adequate shape constraint, 62 polygons that do not fulfil the requirements described above, were excluded. After applying these three constraints, 318 sites were found to be suitable for locating a biogas plant, with areas from 1 ha to 35.4 ha.

The suitability map (Fig. 2), corresponding to the condition of the study that represents the suitability or unsuitability of a certain place, shows that a large portion of the area under analysis is unsuitable due to one or more constraints.

3.2. Application of ELECTRE TRI considering the suitable polygons as alternatives

In this phase ELECTRE TRI was applied to 318 sites classified to be suitable as alternatives, for each scenario (Best and Worst) in order to classify each of the alternatives. The following results were obtained (Fig. 3):

- 245 alternatives (suitable polygons) were classified as Category 1, i.e., low suitability;
- 9 alternatives were classified as Category 2, i.e., medium suitability;
- 1 alternative was classified as Category 3, i.e., high suitability;
- 22 options ranging from low to medium suitability (Category 1 in the worst scenario and Category 2 in the best scenario, defined as Category 1–Category 2);
- 20 alternatives vary between low and high suitability (Category 1 in worst scenario and Category 3 in the best scenario, defined as Category 1–Category 3);
- 21 alternatives ranging from medium to high suitability (Category 2 in worst scenario and Category 3 in the best scenario, defined as Category 2–Category 3).

This means that out of 318 alternatives, 255 obtain the same category in both scenarios and 63 alternatives are not definitively classified. To obtain a more detailed classification of the areas for which the two scenarios do not coincide, these areas were partitioned by means of grids.

3.3. Application of ELECTRE TRI considering vector grids as alternatives

For a better classification of the 63 polygons not definitively classified, having areas between 1.1 ha and 35.4 ha, in the

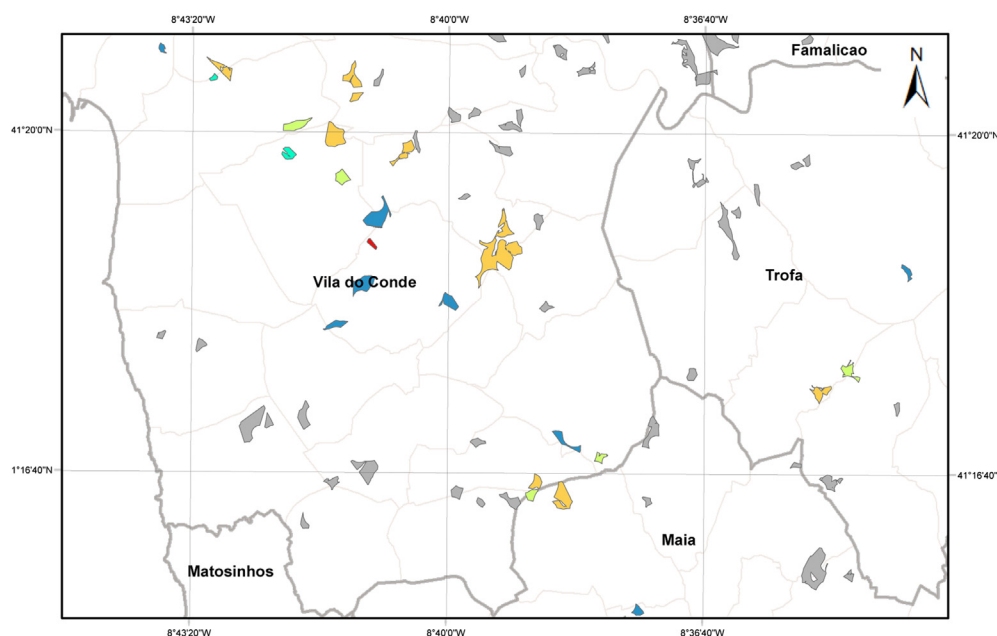

Fig. 3 – Classification of the polygons meeting the constraints, considering the best and worst values for each polygon (map detail).

Fig. 4 – Classification of the smaller areas (vector grid), considering the best and worst values for each site (map detail).

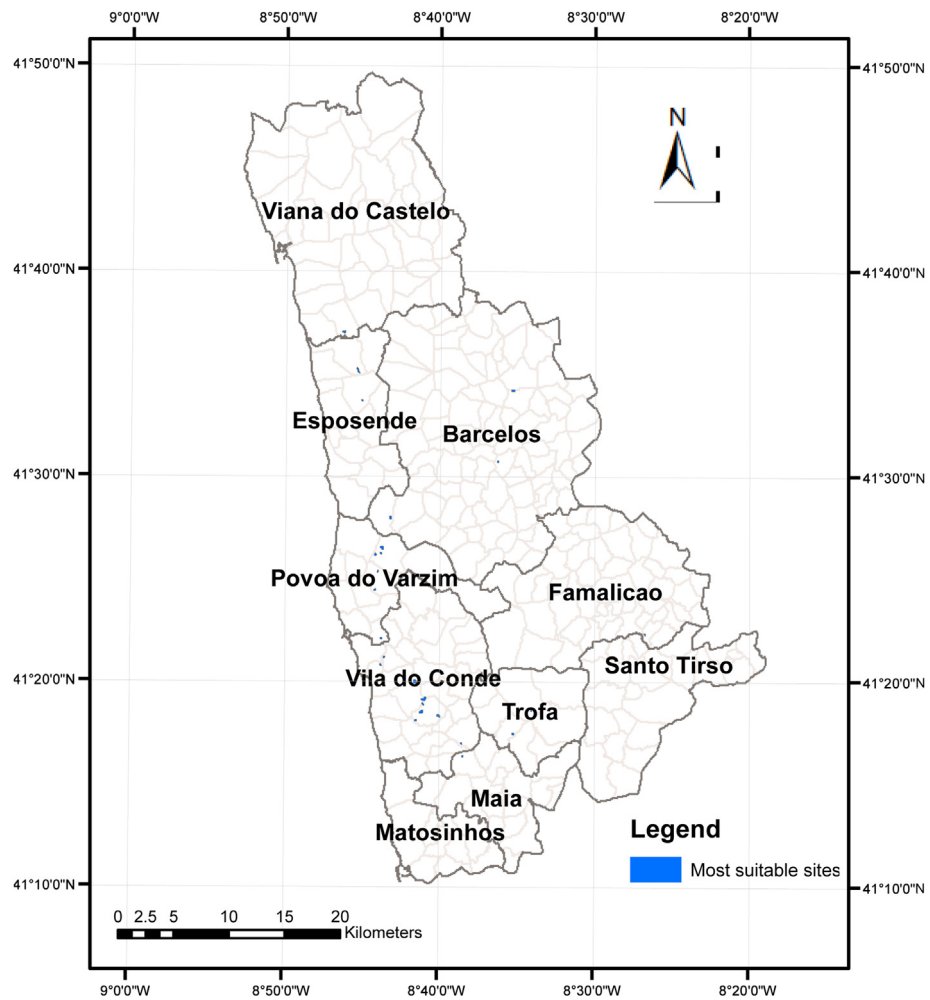

Fig. 5 – Final map of the most suitable sites for siting biogas plant.

second phase a sub-division of these sites with a vector grid was considered in order to obtain a more specific classification. In this study, quadrangular grids with 2 ha were built using the ET GeoWizards tool.

By intersecting this quadrangular grid with the 63 unclassified suitable sites, 513 grids were obtained. It is also necessary to require that each of them has the required minimum area of 1 ha, eliminating 389 grids. This yields 124 grids with the required area but some of them do not have the appropriate shape for the implementation of biogas plants. By imposing the condition that compactness ≥ 0.40 , we obtained 109 grids, i.e., 15 have been eliminated.

Using the ELECTRE TRI for both scenarios (Worst and Best), taking into consideration these 109 Vector grids as alternatives, the following results were obtained (Fig. 4):

- 31 alternatives (suitable sites) are classified as Category 1, i.e., low suitability;
- 11 alternatives are classified as Category 2, i.e., medium suitability;
- 1 alternative is classified as Category 3, i.e., high suitability;
- 31 options ranging from low to medium suitability;
- 3 alternatives vary between low and high suitability;
- 32 alternatives ranging from medium to high suitability.

Taking into consideration these restrictions (minimum size and adequate shape) and the fact that the creation of the grids by ET GeoWizards is automated, some of the 63 suitable sites do not contain grids. Fifteen suitable sites are in this situation: five are classified as category 1 in the worst scenario and category 2 in the best; four are classified as category 1 in the worst scenario and category 3 in the best and seven are classified as category 2 in the worst scenario and category 3 in the best.

Overall, we obtained:

- 39 sites classified as Medium-High suitability (classified as category 2 in the worst scenario and category 3 in the best scenario), of which 32 appeared as grids and 7 as suitable polygons;
- 2 sites classified as High Suitability are added to this: one being a grid and the other one a suitable polygon. The area of the most suitable sites varies between 1.038 and 2.215 ha.

These 41 sites deemed to be the most interesting ones for locating biogas plants are spread over eight counties (Fig. 5): Barcelos, Esposende, Maia, Póvoa de Varzim, Trofa, Viana do Castelo, Vila do Conde and Vila Nova de Famalicão, and about 46% of sites are located in the county of Vila do Conde, 19.5% in the county of Póvoa de Varzim, 12.2% in Barcelos and 7.32% in Esposende. In addition to polygon distributing across counties, we also analysed the distribution across parishes (Table 5).

3.4. Discussion

The results show that this GIS-based model, by integrating both spatial data and non-spatial information, is capable of providing a broad-scale and multidimensional view on the potential bio-energy systems development in the area of

study to account for constraints as well as economic, environmental and social factors.

The suitability of development projects depends, to a large extent, on the integration of local knowledge with scientific inputs from the stakeholders (e.g. planners, local governments, electric utilities, dairy farmers and other interested parties) in the decision-making process, so the involvement of more experts and decision makers will be necessary to eventually implement decisions based on this type of approach.

The main limitation of this work is that the amount and location of animal waste sources to be used by a biogas plant was not taken into account. This can be addressed by facility location optimization models able to consider the amount of waste needing to be processed on each farm and the road network. Such models usually have a large size. Nevertheless, the work developed in this paper allows such a location model to be much easier to solve, since it already identifies a small number of candidate locations.

4. Conclusions

Multicriteria Spatial Decision Support Systems, with integration of GIS and MCDA, constitute a very promising research line in the broad field of suitability assessments of land-use and, particularly, in that of undesirable facilities location problems, thanks to the greater effectiveness and efficiency gained by the spatial decision-making process. This study presents an innovative approach to the GIS/ELECTRE TRI methodology, in consideration of two scenarios and the iterative application of the method, (firstly) considering suitable sites as alternatives and (secondly) vector grid cells as

alternatives, and considering the variability of the site's geographical characteristics from one zone to another (factor homogeneity inside each alternative location).

Using the resulting suitability map the decision makers can make decisions based on better knowledge of land-use suitability. The domain experts assumed a technical (vs. political) perspective when setting the ELECTRE TRI parameters. Reaching a final decision can benefit from involving the local authorities and other stakeholders, who may weigh differently the evaluation criteria and may bring concerns of a more political nature. Therefore, although land plots excluded by the hard constraints or poorly classified by the ELECTRE TRI model are clearly alternatives to be excluded, land plots with a good classification are not necessarily politically acceptable alternatives for siting a plant.
