## Vibrational Spectra and Phase Transition in Triglycine Sulpho-Phosphate

Infrared and single crystal Raman spectra for various polarization geometries of Triglycine Sulpho-Phosphate (TGSP) have been recorded and analysed. The bonds of hydrogen atoms in  $\text{H}_2\text{SO}_4$  and  $\text{H}_3\text{PO}_4$  groups are shown to be weak and the possibility of proton transfer from  $\text{H}_2\text{SO}_4/\text{H}_3\text{PO}_4$  group is indicated. Two different types of glycinium ions are shown to be present in the unit cell. Temperature dependent Raman spectra of TGSP have been recorded. The phase transition detected around 325 K in TGSP is explained in terms of the flipping motion of the glycinium ion and of attaining a higher crystal symmetry.

### Introduction

IR and Raman spectral investigations of Triglycine Sulphate (HADNI et al.; GRANDJEAN et al.; KHANNA et al.; TAUREL et al.; DODD.; WINTERFELDT et al.; BARKER JR, TINKHAM; KRISHNAN, BALASUBRAMANIAN; GALUSTIAN) have received considerable attention because of its ferroelectric properties and its applications in developing infrared detectors. HADNI et al. studied the dielectric and thermal properties of TGS and triglycinefluoroberylate. The influence of inorganic ions has been studied by GAFFER et al. They have shown that doping with  $\text{Cu}^{2+}$ ,  $\text{Mg}^{2+}$  and  $\text{Cr}^{3+}$  considerably reduced the ability of TGS to convert mechanical energy to electrical energy while this ability slightly increased at room temperature when admixed with  $\text{Fe}^{3+}$ . It has been found that the replacement of  $\text{SO}_4$  by  $\text{BeF}_4$  or  $\text{SeO}_4$  group in TGS alters the transition temperature and other ferroelectric properties considerably (WINTERFELDT et al.; BLINC et al.). In the present study, an investigation has been made to analyse the vibrational spectra of  $\text{TGS}_x\text{P}_{1-x}$  ( $x = 0.5$ ) and the temperature dependence of low frequency modes above and below the transition temperature.

### Experimental

Single crystals of triglycine sulpho-phosphate (TGSP) are synthesised from AR grade glycine, sulphuric acid, and orthophosphoric acid (NATARAJAN et al.) in the stoichiometric ratio. Good optical quality single crystals are used to record the Raman spectra in the  $90^\circ$  scattering geometry, for the four orientations  $Z[\text{YY}]\text{X}$ ,  $Z[\text{XY}]\text{X}$ ,  $Z[\text{YZ}]\text{X}$  and  $Z[\text{XZ}]\text{X}$  using a Spex Ramalog 1401 spectrometer. The green line at 514.5 nm generated by an  $\text{Ar}^+$  ion laser operating at 80 mw power, is used as the source. Bruker IFS-85 ( $4000-500\text{ cm}^{-1}$ ) and Bio-Rad FTS-7 ( $500-200\text{ cm}^{-1}$ ) FT-IR spectrometers are used to obtain the IR spectra with the sample in KBr.

The structural data are collected on a ENRAF-NONIVS diffractometer with  $\text{MoK}_\alpha$ -radiation to confirm the crystal structure of TGSP.

T = translations; R = librations

### Interpretation of the spectra

#### Crystal Structure and Factor group analysis

The comparison of the results of X-ray analysis and the calculation of Z-value from density measurements of TGSP with the corresponding values for TGS confirms that they are isostructural. Hence the space group of TGSP is taken as  $P2_1$ .

The structural parameters of TGSP are:

$$\text{Space group } P2_1; \quad Z = 2$$

$$a = 9.1651 \text{ \AA}; \quad b = 12.6265 \text{ \AA}; \quad c = 5.7348 \text{ \AA}$$

$$\beta = 105^\circ 63'; \quad d = 1.863 \text{ g/cm}^3$$

The factor group analysis using the standard correlation method (FATELEY et al.) has been carried out with  $NH_3$ ,  $CH_2$ ,  $(P,S)O_4$  and the six hydrogen atoms in general positions. Excluding the acoustical modes 225 normal modes are predicted (Tab. 1).

#### $(P,S)O_4$ vibrations

Since the positions of P and S atoms are not distinguishable and the masses of S and P atoms are very close to each other, the frequencies of similar modes of  $PO_4$  and  $SO_4$  groups are expected to be very close with a possibility of overlapping of bands. Hence, independent assignments of  $PO_4$  and  $SO_4$  groups are very difficult.

### Stretching modes of (P,S)O<sub>4</sub>

As the symmetric stretching mode  $\nu_1$  of (P,S)O<sub>4</sub> group is expected to be the most intense and polarized in the Raman spectrum, the band at  $978\text{ cm}^{-1}$  is easily assigned to this mode. In IR this is observed as a weak band at  $973\text{ cm}^{-1}$ . The activation of this inactive IR mode is due to the site symmetry effect.

When PO<sub>4</sub> and SO<sub>4</sub> groups go inside the unit cell to build up the crystal, forces due to the potential field of the neighbouring ions are likely to distort the tetrahedral symmetry of the groups thereby causing the removal of degeneracy of the degenerate vibrations. The triply degenerate asymmetric stretching mode  $\nu_3$  expected to occur in the region  $1100$  to  $1050\text{ cm}^{-1}$  (CHAPMAN et al.) is observed as two bands in the three polarization geometries [Z[YY]X:  $1087, 1116\text{ cm}^{-1}$ ; Z[XY]X:  $1085, 1113\text{ cm}^{-1}$ ; Z[XZ]X:  $1095, 1110\text{ cm}^{-1}$ ]. In Ir, all the expected components are observed at  $1054, 1086, \text{ and } 1128\text{ cm}^{-1}$ .

The degeneracy of the symmetric bending mode  $\nu_2$  is lifted in IR ( $460, 488\text{ cm}^{-1}$ ) due to crystal field effect. In the Z[XY]X, Z[YZ]X, Z[XZ]X spectra one band each is observed, whereas two bands are observed in the Z[YY]X spectrum. Two bands each are observed in the polarization geometries Z[YY]X, Z[XY]X, Z[XZ]X for the triply degenerate asymmetric bending mode. In IR also two bands ( $618$  and  $675\text{ cm}^{-1}$ ) are observed. The complete assignments are listed in Table 2.

In compounds having H<sub>2</sub>SO<sub>4</sub> und H<sub>3</sub>PO<sub>4</sub> groups, polarized (P, S)–O(H) stretching is expected around  $860\text{ cm}^{-1}$  with high intensity (CHAPMAN et al.). In the present case, a wide range of frequencies ( $890$ – $915\text{ cm}^{-1}$ ) has been observed in the different orientation [Z[YY]X;  $890$  and  $900\text{ cm}^{-1}$  Z[XY]X;  $900$  and  $915\text{ cm}^{-1}$  and Z[XZ]X;  $892\text{ cm}^{-1}$ ]. The corresponding IR band is observed at  $902\text{ cm}^{-1}$ . The high values obtained for the stretching frequencies show that the hydrogen atom is loosely bound to the oxygen atom of (P, S)O<sub>4</sub> group. As expected, the (P, S)–O(H) in-plane and out-of-plane bending frequencies are observed in the regions  $1200$ – $1300\text{ cm}^{-1}$  and  $800$ – $820\text{ cm}^{-1}$ , respectively, with lower intensity.

### Vibrations of glycine molecule

For the glycine cation (TAKEDA et al.); the C=O stretching frequency of the un-ionized carboxylic group is usually found near  $1740\text{ cm}^{-1}$  as an intense band in IR. The ionized carboxylic group is known to give rise to two principal stretching frequencies; an asymmetric stretching frequency in the region  $1600$ – $1560\text{ cm}^{-1}$  and a symmetric stretching frequency near  $1400\text{ cm}^{-1}$  (RAO; PEARSON, SLIFKIN; TAKEDA et al.). The observed IR spectrum has three intense bands at  $1738, 1703, \text{ and } 1536\text{ cm}^{-1}$  and one medium intense band at  $1423\text{ cm}^{-1}$ . This strongly suggests that TGSP contains both ionized and unionized carboxylic groups. From detailed analysis of the vibrational spectra of TGS it has been shown that the TGS contains the non-planar  $\text{NH}_3^+\text{CH}_2\text{COOH}$  and the planar  $\text{NH}_3^+\text{CH}_2\text{COOH}$  and  $\text{NH}_3^+\text{CH}_2\text{COO}^-$  forms (WINTERFELDT et al.). These ions are interconnected by a network of hydrogen bonds. As both TGS and TGSP have identical structure and ionized and unionized carboxylic groups are found to exist in TGSP, it is justified to assume that the glycinium group exist in the forms  $\text{NH}_3^+\text{CH}_2\text{COO}^-$  and  $\text{NH}_3^+\text{CH}_2\text{COOH}$ . In the later form the protonation is at the expense of protons from the H<sub>2</sub>SO<sub>4</sub>/H<sub>3</sub>PO<sub>4</sub> groups. This is supported by the absence of NH<sub>2</sub> in the spectrum as discussed below.

<sup>a</sup> s = strong, m = medium; w = weak, v = very; sh = shoulder; br = broad;<sup>b</sup>  $\delta$  = bending;  $\nu$  = stretching; r = rocking;  $\omega$  = wagging; l = librations, t = translations;  $\gamma$  = out-of-plane bending Subscripts as and s refer to asymmetric and symmetric vibrations, respectively

The stretching modes of  $\text{CH}_2$  group usually occur in the  $3100 - 2800 \text{ cm}^{-1}$  region (COLTHUP et al.). In the Raman spectra the  $\nu_s \text{CH}_2$  is expected to be intense, sharp and polarized, whereas  $\nu_{as} \text{CH}_2$  is unpolarized. The observed polarized bands at  $2960$  and  $2986 \text{ cm}^{-1}$  in the  $\text{Z}[\text{YY}]\text{X}$  orientation are easily assigned to the  $\nu_s \text{CH}_2$  mode. Since the Raman band at  $3018 \text{ cm}^{-1}$  is unpolarized, it is assigned to  $\nu_{as} \text{CH}_2$ . In the IR spectra there is a very intense broad band extending from  $3600 - 2400 \text{ cm}^{-1}$  ( $\text{FWHM} \sim 625 \text{ cm}^{-1}$ ) with peaks at  $3017$ ,  $3110$  and  $3200 \text{ cm}^{-1}$ . Since this broad frequency range contains  $\text{NH}_3^+$  and  $\text{CH}_2$  group vibrations, an unambiguous identification of their vibrational modes from the IR spectra has not been possible. The CH scissoring vibrations of the  $\text{CH}_2$  group is observed at  $1440 \text{ cm}^{-1}$  in Raman and at  $1465 \text{ cm}^{-1}$  in IR. The CH wagging and twisting vibrations are observed in the region  $1300 - 1370 \text{ cm}^{-1}$ . The frequencies observed here for these modes are in complete agreement with those of TGS and  $\alpha$ -glycine (WINTERFELDT et al. KRISHNAN, BALASUBRAMANIAN).

It is well established that the uncharged amino group  $\text{NH}_2$  have stretching frequencies in the  $3500 - 3300 \text{ cm}^{-1}$  range while the charged species  $\text{NH}_3^+$  have stretching frequencies in the  $3300 - 2500 \text{ cm}^{-1}$  range (EDSALL, SCHEINBERG; LINDGREN et al.; DURIG et al.). Furthermore the  $\text{NH}_3^+$  stretching bands are broader and weaker than those arising from the uncharged  $\text{NH}_2$  groups (BELLAMY; EDSALL, SCHEINBERG). In the Raman spectra, only a very broad medium intense band is observed at  $3176 \text{ cm}^{-1}$  for NH stretching modes. The position and broadness of this band clearly shows that it is due to  $\text{NH}_3^+$  group. The bands observed at  $3100$  and  $3200 \text{ cm}^{-1}$  in the IR spectra also assigned to the stretching modes of  $\text{NH}_3^+$ . From a comparison of the spectrum of TGSP with those of TGS, tricyclicine, and  $\alpha$ -glycine, the following assignments are made. The two IR bands at  $1623$  and  $1653 \text{ cm}^{-1}$  are assigned to  $\delta_{as} \text{NH}_3^+$  and the strong band at  $1502 \text{ cm}^{-1}$  is assigned to  $\delta_s \text{NH}_3^+$ . The band  $1212 \text{ cm}^{-1}$  is assigned to  $\text{NH}_3^+$  rocking vibrations. The  $\text{NH}_3^+$  rocking modes occur at much lower frequencies:  $1112$ ,  $1114$ ,  $1135$  and  $1179 \text{ cm}^{-1}$  in TGS;  $1153$  and  $1162 \text{ cm}^{-1}$  in triglycine and  $1112$  and  $1140 \text{ cm}^{-1}$  in  $\alpha$ -glycine. The difference observed in these frequencies in TGSP could be due to the difference in the disposition and strength of hydrogen bonds.

The mode  $\nu_s \text{CH}_2$  has two components in all the orientations and  $\nu_{as} \text{CH}_2$  has two components ( $3001$  and  $3018 \text{ cm}^{-1}$ ) in the  $\text{Z}[\text{YZ}]\text{X}$  spectrum.  $\nu \text{C}=\text{O}$  which is expected to be a singlet appeared as a doublet ( $1703$  and  $1738 \text{ cm}^{-1}$ ) in IR. Two bands are observed also for the mode  $\delta_{as} \text{NH}_3^+$ . If  $\text{NH}_3^+ \text{CH}_2 \text{COOH}$  exists only in one form this doubling is improbable. This doubling is probably due to the existence of both planar and non-planar the ( $\text{NCCOO}^-$  skeleton is non-planar)  $\text{NH}_3^+ \text{CH}_2 \text{COOH}$  glycinium groups. Bands below  $300 \text{ cm}^{-1}$  are assigned to the external modes. The external modes include  $\text{SO}_4$ ,  $\text{PO}_4$  and glycine translations and librations.

### Temperature effects

Recently, considerable progress has been made in relating phase transition of substance to softening of optical modes and variation in low frequency band profiles (MARCHON, NOVAK; OHNO, LOCKWOOD; MYLRAJAN, SRINIVASAN; RAIMBAULT et al.). In the present investigation, attention is focused on the effect of temperature variation on the external modes of TGSP.

The temperature dependent Raman Spectra (Fig. 1) of TGSP in the  $50 - 300 \text{ cm}^{-1}$  region have been recorded with the help of the variable temperature Raman cell fabricated in our

Fig. 1. Raman spectra of triglycine sulpho-phosphate single crystal using Z[YY]X geometry at different temperatures in the 50–300  $\text{cm}^{-1}$  region

laboratory. Around 325 K, the intense band at  $66\text{ cm}^{-1}$  is found to be shifted to  $70\text{ cm}^{-1}$  with lowering of intensity. Also this band which showed upward shift in frequency with temperature is found to remain constant above  $T_c$ . In TGS, the glycinium groups as a whole are involved in the phase transition apart from the changes in the OH protons (BLINC et al.). Since TGS and TGSP are isostructural it is quite reasonable to assume that the phase transition mechanism in both the compounds will be of identical nature. The unit cell of

TGS contains glycine ( $\text{NH}_3^+\text{CH}_2\text{COO}^-$ ) and protonated glycinium ( $\text{NH}_3^+\text{CH}_2\text{COOH}$ ) groups interconnected by hydrogen bonds. During phase transition the proton transfer between these groups results in polarization reversal and an exchange of the role of glycinium and glycine groups. Thus the proton transfer between glycinium and glycine groups around  $T_c$  may result in a frequency shift for internal and external modes. As in the case of TGS, the observed frequency shift is explained due to the flipping motion between glycine and glycinium groups, whereas the lowering of intensity could be due to the crystal attaining higher symmetry as it undergoes a phase transition. Since this phase transition is not accompanied by the presence of any prominent soft mode it is evident that the transition is of order-disorder type.

### Results

1. Even though  $\text{H}_2\text{SO}_4$  and  $\text{H}_3\text{PO}_4$  groups do exist, the bonding of their hydrogen atom to the sulphate/phosphate oxygen is not strong.
2. The presence of both (P, S) $\text{O}_4$  and (P, S)–O(H) stretching frequencies indicates the possibility of proton transfer between  $\text{H}_2\text{SO}_4/\text{H}_3\text{PO}_4$  groups.
3. There are two different types of glycinium ions present in the unit cell.
4. TGSP is found to undergo a phase transition around 325 K which is detected from the changes in frequency and intensity in the Raman band. The observed frequency shift and intensity changes during phase transition are explained in terms of a flipping motion of the glycinium ion and of attaining a higher crystal symmetry.
